14 Abstract

Methods for measuring recreational water quality vary in analysis time, precision, 15 availability, and cost. Decision-makers often use predictions from statistical mod-16 els to compensate for the shortcomings of available measurements. However, model 17 validation and comparison has largely omitted measurement error (defined here as 18 variation in both sampling and the measurement technique) as an important source 19 of uncertainty during validation. It is unknown how this omission affects estimates of 20 model performance and comparisons between models. This study aims to fill this gap. 21 First we derive the bias incurred when omitting measurement error in calculating a 22 model's mean squared error. We then develop a non-parametric validation method to 23 correct estimates of mean squared error. To study other metrics of prediction perfor-24 mance (mean absolute error, sensitivity, precision, etc.) we develop a second validation 25 method that uses simulations from a Bayesian validation model. These methods are 26 applied to a comparison of two prediction models (random forest and nearest neighbor) 27 used to predict the level of fecal indicator bacteria at 9 recreational beaches in the city 28 of Chicago. We find that accounting for measurement error significantly changes esti-29 mates of model performance. Moreover it reveals substantial uncertainty underlying 30 some of these estimates. 31

32 1 Introduction

33 Recreational waterways are subject to contamination by bacteria from various sources including stormwater, sewage, and wildlife (Whitman & Nevers, 2008). To 34 mitigate the public's exposure to contaminated water and associated gastrointestinal 35 illness (Prüss, 1998), managers of recreational beaches monitor the presence of fecal in-36 dicator bacteria (FIB) as a proxy measure of contamination. Managers issue warnings 37 or close sites based on this information. There is a trade off between the protective 38 public health benefits of these actions and the recreational benefits of access to wa-39 terways (Rabinovici et al., 2004). A major challenge in this decision process is how 40 to appropriately account for measurement error in FIB data, which can be substan-41 tial (Whitman & Nevers, 2004; Whitman et al., 2010). Here we define measurement 42 error as the combined effect of error in the measurement process and in-situ sampling 43 variability. 44

Measurement error has long been recognized as a major issue in water resources 45 management, and the literature is rich with methods to incorporate measurement 46 uncertainty in modeling and decision analysis. In hydrology, for example, Bayesian 47 rainfall-runoff models have been developed to account for significant measurement error 48 in catchment-scale precipitation to support improved parameter inference, predictive 49 uncertainty bounds, and structural error diagnostics (Kuczera et al., 2006; Vrugt et 50 al., 2008; Renard et al., 2011). Similar methods have also been extended to urban 51 stormwater models to propagate bias and variance in both input (e.g. rainfall) and 52 calibration (e.g., stormwater quality) data through the model fitting process (Dotto 53 et al., 2014). Accommodations for measurement error have also been incorporated 54 into decision-making processes, for instance with respect to groundwater remediation. 55 For example, (Liu et al., 2012) used a value-of-information approach to estimate re-56 mediation cost reductions afforded by reduced model, parameter, and measurement 57 uncertainty. Likewise, (Leube et al., 2012) used Bayesian methods to consider the ef-58 fect of integrated groundwater modeling uncertainties (including measurement error) 59 on optimal sampling design. 60

Measurement error has also played a prominent role in recreational water quality analysis. Modeling in this literature is often oriented towards decision support, where model-based predictions of FIB concentrations (including estimated moments or percentiles of measured data) are compared to water quality standards to guide

management actions. A significant body of work has considered the impacts of mea-65 surement error on these decisions. For instance, several studies have used Bayesian 66 analyses to explore the potential of concentration-based FIB standards that account 67 for measurement error in indirect FIB concentration proxy measures (Gronewold et 68 al., 2008; Gronewold & Borsuk, 2010; Gronewold et al., 2017). A similar approach was 69 used to show that a significant fraction of space-time variability in FIB proxy measures 70 is driven by errors in measurement techniques and not underlying variability of in-situ 71 FIB concentrations (Gronewold et al., 2013). 72

73 When trying to improve water quality management decisions in the presence of model structural uncertainty, it is also common to compare the predictive performance 74 of multiple FIB concentration models. In this facet of recreational water quality mod-75 eling, however, measurement error has been given less attention. When validating 76 prediction models, we found that researchers often ignored measurement error, simply 77 assuming that a measurement (or mean of multiple measurements) represented the true 78 bacteria level (Nevers & Whitman, 2011; Francy, 2013; Shively et al., 2016; Lucius et 79 al., 2019). This is true even in studies that consider measurement error in the model 80 estimation process (e.g., see figure 5 and associated discussion in Gronewold et al. 81 (2011)). The omission of measurement error thus distorts a comparison of prediction 82 performance across models, although the magnitude of this effect is unknown. 83

Given the methodological gap above, this study contributes two methods for 84 model validation that account for measurement error when evaluating and comparing 85 the performance of prediction models. The first is a non-parametric method that makes 86 minimal assumptions but is limited to a single metric of model performance, namely 87 mean squared error (MSE). The second is a Bayesian method that uses simulation from 88 the posterior distribution of a Bayesian measurement error model. This method has 89 the advantage of being applicable to any metric of model performance, including those 90 assessing the utility of predictions for decision-making around management-relevant 91 FIB thresholds. 92

These methods are generally applicable to any inter-model comparison, and are 93 thus relevant across a range of modeling exercises in water quantity and quality anal-94 ysis, not to mention other domains. However, they are particularly relevant to recre-95 ational water quality modeling given the common task of comparing multiple FIB 96 concentration models for decision support and the high degree of measurement er-97 ror in these data. We thus demonstrate the approach in a case study of recreational 98 beaches in Chicago, which has been used extensively to compare statistical models 99 that aid in prediction of bacteria levels (Nevers & Whitman, 2011; Shively et al., 2016; 100 Lucius et al., 2019). 101

¹⁰² 2 Materials and methods

In our analysis we present both prediction models (section 2.2) and validation 103 methods (2.3). The prediction models are used to predict FIB levels at unsampled 104 beaches to support beach management decisions. The validation methods are used 105 to evaluate and compare these prediction models and their resulting decisions. The 106 focus of this study is on the methods for validation, not the specific prediction models 107 being validated. We compare a commonly used method for validation (termed naive 108 validation) against two new methods (a non-parametric method and Bayesian method) 109 that account for measurement error. We note that Bayesian validation relies on an 110 auxiliary model (termed the Bayesian validation model), which is used strictly to 111 validate other prediction models and not for prediction itself (more detail given in 112 section 2.3.4). 113

114 2.1 Study site and data

The city of Chicago has 23 beaches along approximately 42 km of the Southwest shoreline of Lake Michigan. Of these, 19 beaches (figure 1) are currently subject to FIB monitoring during the swimming season from late May to early September. The beaches receive about 20 million visits during this period each year (Nevers & Whitman, 2011).

Traditionally, administrators collected two samples per site for culture measurement of *E. coli* in terms of colony forming units (CFU) per 100 mL. Management decisions were made on the basis of the geometric mean measurement exceeding 235 CFU/100 mL. Culture measurements take at least 12-24 hours due to the bacteria incubation period. Because water quality can change rapidly, decisions based on measurements that are subject to such delays are likely to result in unnecessary closures as well as exposure (Kinzelman et al., 2003).

Starting in 2015, quantitative polymerase chain reaction (qPCR) measurements 127 of *Enterococci* have been employed. This method quantifies indicator bacteria in less 128 than two hours in terms of cell equivalents (CE) by comparing the sample to a calibra-129 tor with known number of *Enterococci* cells. A subset of these measurements are shown 130 131 in figure 1. For details and comparisons of culture and qPCR measurements and their consequences see Noble et al. (2010), U.S. EPA (2012), and Dorevitch et al. (2017). 132 Managers in Chicago currently estimate FIB levels at each beach each day using the 133 geometric mean of two qPCR sample measurements. Management decisions are made, 134 following U.S. EPA guidance (U.S. EPA, 2012), based on this estimate exceeding 1000 135 CE/mL. 136

Due to the cost of these measurements (Whitman et al., 2010) and the historical 137 correlation of FIB levels between sites, the city has proposed reducing sampling to 138 ten beaches and using a random forest (RF) model to predict levels at the remaining 139 beaches (Lucius et al., 2019). The sampled beaches were chosen as follows. First, five 140 beaches were selected to be sampled due to their historically high FIB levels. Next, 141 the remaining beaches were grouped into five geographic clusters. Five beaches were 142 selected to be sampled, one from each cluster. The five historically high FIB sites and 143 five cluster representatives together give 10 sampled beaches, leaving 9 sites at which 144 to make predictions (see figure 1). The prediction model uses daily meteorological and 145 hydrological covariates collected between 2015-2019 for the months of May-September. 146

147

2.2 Prediction models of bacteria levels at unsampled sites

In this study we (re-)evaluate the predictions and management consequences of 148 the RF model, and compare its performance against a benchmark NN model. The RF 149 and NN models both serve as candidate *prediction* models. The purpose of this work 150 is to assess how to validate and compare performance across prediction models given 151 measurement error in the observations. We use the RF and NN prediction models 152 to demonstrate our validation methods, but note that other prediction models could 153 have been used for this purpose. Prior to describing the validation methods that are 154 the focus of this work (see section 2.3), we first introduce notation and details of the 155 specific predictive models used in the case study. 156

¹⁵⁷ We denote the true (unobserved) level of *Enterococci* natural log cell equivalents ¹⁵⁸ per mL (log CE/mL) by θ_{jt} with $j = 1 \dots J$ a site index and $t = 1 \dots T$ a day index. ¹⁵⁹ Let Y_{ijt} be the observed measurements of θ_{jt} . In our case we typically have two ¹⁶⁰ measurements Y_{1jt} , Y_{2jt} which are replicates, taken at the same time and location.

Here we present NN-based and RF-based predictions of θ_{jt} at the prediction sites *j*. On day *t*, both predictions are based on the input vector of mean FIB measurements

(A) Map of study sites

Figure 1: (A) Map of the 19 recreational beaches in Chicago on Lake Michigan (see inset for location within the Great Lakes) showing sample and prediction sites according to the proposed targeted sampling design of Lucius et al. (2019) described in section 2.2.2 and (B) daily fecal indicator bacteria levels during the 2019 beach season at three nearby sites. Gray circles are qPCR measurements (typically 2 per site per day), black line connects daily mean measurements, red region is 95% interval of Bayesian validation model posterior, and dashed line indicates action threshold of log 1000 cell equivalents (CE) per mL.

 Y_{jt} at the proposed ten sampled sites (figure 1). The RF prediction employs an additional input vector of K covariates X_{jt} varying by date and site. The outputs are predictions of the true FIB level at the proposed nine prediction sites.

166 2.2.1 Nearest neighbor (NN) prediction model

For prediction site j, let n(j) be the index $(1, \ldots, J)$ of the geographically nearest sampled site (figure 1A). The NN model predicts the FIB level at site j on date t to be equal to the mean level at this neighbor on the same date:

$$\hat{\theta}_{jt}^{\mathrm{nn}} = \bar{Y}_{n(j),t}.\tag{1}$$

¹⁶⁷ This model serves as a simple but practical benchmark.

168

174

175

176

180

2.2.2 Random forest (RF) prediction model

Lucius et al. (2019) proposed a "hybrid nowcast model" using a RF regression model with 400 trees (Breiman, 2001). The outcomes used to fit the model were the mean FIB levels at the prediction sites. The inputs to the model were the mean levels at the sampled sites together with covariates. Formally we can write the prediction model as a vector of functions

$$\hat{\theta}_{jt}^{\rm rf}(\bar{Y}_t^{\rm sample}, X_{jt}) \tag{2}$$

where X_{jt} is a vector of K = 11 covariates (varying by site and date) and $\bar{Y}_t^{\text{sample}}$ is the vector of average measurements at the ten sample sites on date t. For this study we refit the RF using our training set, which is larger than that of Lucius et al. (2019). The covariates X_{jt} mirror those of the original publication:

- Precipitation: 1 and 2-3 day total rainfall, 1-2 day change in water level
 - Sunlight: 1 and 2-3 day average cloud cover
 - Wind: 1 day average N/S/E/W wind speed
 - Time: day of year, weekday indicator

where the weekday indicator is an indicator for whether the date is a weekday or weekend and 1 day, 1-2 day, and 2-3 day covariates aggregate over the period 24 hours, 24-48 hours, and 48-72 hours prior.

The above are prediction models of continuous FIB levels, but decisions are based 181 on the binary event of exceeding 1000 CE/mL (section 2.1), for which an FIB level 182 prediction must be transformed into a binary exceedance prediction. Some of our 183 performance measures (e.g. precision) evaluate these exceedance predictions. For the 184 baseline NN prediction model, we predicted an exceedance whenever the predicted FIB 185 was greater than the 1000 CE/mL threshold. Since the RF is known to produce biased 186 predictions, Lucius et al. (2019) calibrated a custom threshold so that the resulting 187 specificity (equivalently false positive rate) matched that of a reference model. We 188 follow this approach, taking NN as the reference model. 189

Exceedance could alternatively be predicted by modeling the binary outcome directly, i.e. classification. However, we continue the standard practice in FIB prediction of modeling the continuous outcome, i.e. regression, as this uses all available information and allows us to use a single model for both continuous and binary outcomes.

^{2.2.3} Calibration of exceedance predictions

2.3 Validation methods for estimating prediction model performance

194

220

The purpose of this study is to develop an approach to compare the performance 195 of the above prediction models in the presence of measurement error. In validation 196 we evaluate the fidelity of predicted states $\hat{\theta}$ to the true state θ by a function $L(\theta, \hat{\theta})$. 197 Here L is one of various performance metrics (e.g. MSE) and θ and θ are restricted 198 to the prediction sites (figure 1) and dates t in a *test period* which we choose to be 199 the most recent beach season, 2019. The RF model was fit using data from a training 200 period, i.e. prior to 2019; the NN model does not require any fitting. We used a single training and test set, known as hold-out validation (Schneider & Moore, 2000), for simplicity. All of the methods below can be easily adapted for cross-validation with 203 multiple folds. 204

Our challenge in validation is that we never observe θ_{jt} . In the literature, θ_{jt} is often assumed to be exactly equal to the mean measurement \bar{Y}_{jt} (Nevers & Whitman, 207 2011; Francy, 2013; Shively et al., 2016; Lucius et al., 2019). Note that it is because these sites were in fact sampled that we can conduct this validation.

However, this method does not account for measurement uncertainty and it is unclear what the consequences of this omission are regarding the overall performance assessment of a prediction model or the comparison of multiple models. We term this method of validation *naive*, and propose two additional methods: *non-parametric* and *Bayesian*. The validation methods are described below and summarized in figure 2.

Note that there are two sources of variation accounting for the difference between the true FIB level θ_{jt} and an observation Y_{ijt} . The first is sampling variation due to the fact that a water sample is taken at a specific point in time and space (Whitman & Nevers, 2004). The second is measurement variation due to the qPCR technology used to analyze the sample (Whitman et al., 2010). As stated earlier, we define measurement error as the combination of these sampling and analysis variations.

2.3.1 Naive validation not accounting for measurement error

In naive validation we simply assume that the mean measurement is true: $\theta_{jt} = \bar{Y}_{jt}$. Then we can evaluate $L(\theta, \hat{\theta})$ as a point estimate of the performance (in contrast to non-parametric and Bayesian validation which estimate performance distributions). The use of naive validation is potentially flawed since the mean observation does not account for measurement error.

When the metric L is MSE, we can explicitly analyze the effect of measurement error. Assume a measurement error model

$$Y_{ijt} = \theta_{jt} + \epsilon_{ijt} \tag{3}$$

where ϵ_{ijt} are independent identically distributed measurement errors, defined as the sum of sampling and analysis errors. We do not assume a measurement error distribution but assume the errors have fixed (finite) variance $\operatorname{Var}(\epsilon_{ijt}) = \tau^2$ independent of the measurement number *i*, site *j*, and date *t*. Then with \mathbb{E} denoting expectation over the random measurement errors ϵ we have

$$\mathbb{E}|\hat{\theta}_{jt} - \bar{Y}_{jt}|^2 = \mathbb{E}|\theta_{jt} + \bar{\epsilon}_{jt} - \hat{\theta}_{jt}|^2 \tag{4}$$

$$= \mathbb{E}[|\theta_{jt} - \hat{\theta}_{jt}|^2 + |\bar{\epsilon}_{jt}|^2 - 2\bar{\epsilon}_{jt}(\theta_{jt} - \hat{\theta}_{jt})]$$
(5)

$$= |\hat{\theta}_{jt} - \theta_{jt}|^2 + \frac{1}{2}\tau^2$$
 (6)

where we used the fact that the ϵ are independent of each other and both θ and $\hat{\theta}$ and there are two errors $\epsilon_{1jt}, \epsilon_{2jt}$ so that $\mathbb{E}[\bar{\epsilon}_{jt}^2] = \frac{1}{2}\tau^2$.

mate $\hat{\epsilon}_{jt} = \hat{\theta}_{jt} - \overline{Y}_{jt}$ of the error, which is averaged across sites j and times t to estimate MSE. The non-parametric method corrects the naive method Figure 2: Validation methods. Prediction models are fit using training (2015-2018) covariates and outcomes, and use testing (2019) covariates to predict testing outcomes. For site j and time t the naive method simply compares the prediction $\hat{\theta}_{jt}$ with the mean observation \bar{Y}_{jt} to give a point estiby incorporating an estimate $\hat{\tau}$ of the measurement error. This is bootstrapped to estimate a sampling distribution. The Bayesian method compares the prediction to a sample of the posterior distribution of the FIB state in a Bayesian validation model that is fit to and conditioned on all the data. For each sample of the posterior $\tilde{\theta}_{jt}^{(s)}$ (indexed by s) there is a corresponding sample of MSE. Abbreviations: mean squared error (MSE). This formula means that under these mild assumptions, the naive estimate of MSE *overestimates* the true MSE by a multiple of the measurement error variance. Thus, the greater the measurement error variance τ^2 , the larger the distortion of naive validation for the particular metric of MSE.

However, since the distortion does not depend on which prediction model is being evaluated (e.g. RF or NN), the naive validation will give an unbiased estimate of the difference in performance, i.e.

$$\mathbb{E}[MSE(\bar{Y},\hat{\theta}^{\mathrm{rf}}) - MSE(\bar{Y},\hat{\theta}^{\mathrm{nn}})] = MSE(\theta,\hat{\theta}^{\mathrm{rf}}) - MSE(\theta,\hat{\theta}^{\mathrm{nn}})$$
(7)

232

2.3.2 Non-parametric validation accounting for measurement error

Equation 4 shows that if we can estimate the measurement error τ then we can correct the bias of the naive estimate of MSE by subtracting it off. If we have more than one FIB measurement per beach-day in the data (as is the case in our data set), we can estimate τ using the standard sample variance estimator, and then average across beaches and days.

Namely if Y_{1jt} and Y_{2jt} are the two observations with measurement error ϵ_{1jt} and ϵ_{2jt} as in equation 3, we define the estimate

$$\hat{\tau}_{jt}^2 = \frac{1}{2} |Y_{1jt} - Y_{2jt}|^2 \tag{8}$$

which is unbiased because

$$\mathbb{E}[\hat{\tau}_{jt}^2] = \mathbb{E}\left[\frac{1}{2}|\epsilon_{1jt} - \epsilon_{2jt}|^2\right]$$
(9)

$$=\tau^2.$$
 (10)

Combining 4 and 9 we have the following estimate for the mean-squared error of $\hat{\theta}_{jt}$:

$$\mathbb{E}[|\hat{\theta}_{jt} - \bar{Y}_{jt}|^2 - \frac{1}{2}\hat{\tau}_{jt}^2] = |\hat{\theta}_{jt} - \theta_{jt}|^2$$
(11)

We average across sites j and dates t to estimate $MSE(\hat{\theta}, \theta)$. We bootstrap this estimate across t to estimate the sampling distribution (unlike naive validation which gives a point estimate).

We emphasize that this result does not make any distributional assumptions. We only assumed that the observations are equal to the true state plus independent measurement error (equation 3). However, this approach is limited to the specific error metric of MSE.

2.3.3 Bayesian validation accounting for measurement error

The approaches to validation presented above either: 1) assume the true FIB level θ_{jt} is equal to the mean of available observations (naive); or 2) indirectly estimate a specific error metric, MSE, under a specific sampling design (non-parametric). An alternative and more general approach is to use a Bayesian model to simulate the latent FIB state θ in validation. This is a form of Monte Carlo uncertainty propagation (ISO, 2009).

²⁵² We start with a Bayesian model (details of which are in section 2.3.4) of the FIB ²⁵³ states and measurements given covariates $(\theta, Y|X)$ fit to all the data (i.e. covariates ²⁵⁴ X and measurements Y). Then we sample θ at the prediction sites from the posterior ²⁵⁵ distribution $\theta|Y, X$ conditioned on all the data. For convenience we write this posterior ²⁵⁶ as $\tilde{\theta}$ and samples indexed by s as $\tilde{\theta}^{(s)}$. Then we can simply evaluate $L(\tilde{\theta}^{(s)}, \hat{\theta})$. Here, as

²⁴⁵

²⁵⁷ in naive and non-parametric validation, $\hat{\theta}$ are RF or NN predictions at the prediction ²⁵⁸ sites based on covariates at those sites and measurements at the sampled sites. By ²⁵⁹ repeatedly sampling $\tilde{\theta}^{(s)}$ and evaluating $L(\tilde{\theta}^{(s)}, \hat{\theta})$ we sample the target distribution ²⁶⁰ $L(\theta, \hat{\theta})|Y, X.$

We emphasize that Y here includes all sites and times. That is, unlike the prediction models which only use observations from the sample sites during the testing period, the Bayesian simulations use measurements from the prediction sites themselves (figure 1). In this way, the Bayesian model can support the validation of other prediction models, but should not be considered a prediction model itself.

Strictly speaking, the Bayesian validation method assumes that the Bayesian 266 validation model is correct. However, it takes into account uncertainty in both model 267 parameters and in observations due to measurement error. Moreover, the method is 268 useful under the weaker assumption that the Bayesian simulations of θ provide a more 269 realistic representation of the true FIB levels against which to compare the prediction 270 models (and infer the target distribution $L(\theta, \hat{\theta})|Y, X$). Additionally, the MSE error 271 metric inferred under Bayesian validation can be validated against the non-parametric 272 approach, which makes fewer assumptions. 273

Yet compared to the non-parametric validation above, which only estimates MSE. 274 Bayesian validation can be used to estimate any prediction performance metric. We 275 consider several, including MSE, mean absolute error (MAE), and the area under the 276 receiver operating curve (AUC) to evaluate predictions of the continuous FIB level. 277 The remaining metrics (precision, sensitivity, specificity) use binary classifications that 278 are obtained from continuous predictions using a threshold (see section 2.2.3). Preci-279 sion measures the proportion of exceedance predictions which are correct; sensitivity 280 measures the proportion of exceedances which are correctly predicted; specificity mea-281 sures the proportion of non-exceedances which are correctly predicted. These latter 282 metrics are particularly relevant to decision-making in recreational water quality man-283 agement, where binary decisions (e.g. site closure) are often based on water quality 284 predictions exceeding a predetermined threshold. 285

286

2.3.4 Bayesian validation model to facilitate Bayesian validation

In order to implement Bayesian validation (section 2.3.3) we need a model of $\theta, Y|X$. Again, this model is not used for prediction, but rather uses all measurements (including those at prediction sites) to simulate the true FIB level θ and thus support validation of other prediction models that only use measurements at the sampling sites. We use a linear regression (on the log scale) model with coefficients varying by site:

$$\theta_{jt} = X_{jt}\beta_j + \eta_{jt} \tag{12}$$

where X_{jt} is a vector of K covariates (see section 2.2.2) and for each site j, β_j is a vector of K regression coefficients, and η_{jt} are model structural errors (distinct from measurement errors modeled below) capturing variation in the true FIB level not explained by the linear regression. We use the same covariates as in the RF (see section 2.2.2) but add an intercept and parameterize the day of year as a B-spline with 4 degrees of freedom (since this model is linear as opposed to the non-linear RF). Thus K = 15.

On top of this regression we add three components. First we add a multivariate normal error distribution with covariance matrix Σ to model correlation in the structural errors across beaches on a given day t:

$$\eta_t \sim \text{Normal}(0, \Sigma) \tag{13}$$

This enables us to combine the measurements at other beaches with those at a given

²⁹⁵ beach in estimating the bacteria level at that beach.

Second we add a multilevel structure on the coefficients, that is we have the second-level regression:

$$\beta_{jk} \sim \operatorname{Normal}(Z\gamma_k, \sigma_{\beta_k}^2)$$
 (14)

where Z is a $J \times L$ matrix of site-level covariates, γ_k is a vector of L second-level 296 regression coefficients, and σ_{β_k} is the second-level residual standard deviation. Specif-297 ically we use L = 3 site level covariates including an intercept, breakwater length, 298 and latitude (which is highly correlated with longitude, see figure 1). This second 200 level regression allows the first level regression (equation 12) between FIB and the 300 observation-level predictors (e.g. precipitation) to vary by site. Moreover, it allows 301 us to partially pool information across sites and incorporate site-level information to 302 more efficiently estimate the coefficients at a given beach (Stow et al., 2009; Cha et 303 al., 2010). Incorporating site-level covariates also supports the (conditional) exchange-304 ability of the sites in the model (Gelman et al., 2013). 305

The final component is an additive and normally distributed measurement error with variance τ^2 (Gronewold et al., 2009):

$$Y_{ijt} \sim \text{Normal}(\theta_{jt}, \tau^2).$$
 (15)

Note that, unlike the RF model which is fit to beach-day mean levels Y_{jt} , the Bayesian model is fit to the individual observations Y_{ijt} .

We put the following uninformative priors on these parameters (Gelman et al., 2013). Decomposing Σ into a correlation matrix Ω and a vector of coefficient scales σ

$$\Sigma = \operatorname{diag}(\sigma) \cdot \Omega \cdot \operatorname{diag}(\sigma) \tag{16}$$

we put a uniform prior over Ω and a Cauchy₊(0,1) prior on the components of σ . The second-level parameters γ_k and $\sigma_{\beta_k}^2$ are given uninformative Cauchy(0,1) and Cauchy₊(0,1) priors, respectively. All priors are defined after standardizing all predictors and the outcome.

We fit the Bayesian validation model using the Markov Chain Monte Carlo software Stan (Carpenter et al., 2017), which uses No-U-Turn sampling (Hoffman & Gelman, 2014), an extension of Hamiltonian Monte Carlo (Duane et al., 1987). We generated 4 chains with 1000 iterations each, saving the last 500 to produce S = 2000samples from the joint posterior parameter distribution. We assessed mixing using the criteria $\hat{R} < 1.05$ and $n_{\text{eff}}/N > .001$ where \hat{R} is the Gelman-Rubin convergence statistic and n_{eff} is the effective sample size (Gelman et al., 2013).

With the uninformative prior on Σ we are making relatively weak assumptions about the covariance structure. This is possible in our application because of the relatively small number (19) of sites and the efficiency of Hamiltonian Monte Carlo. In applications with more sites, it may be useful to model the covariance in terms of the distance between sites j and k using a Gaussian process model or in terms of an adjacency matrix using a conditional autoregressive model (Gelfand et al., 2010).

325 **3 Results**

The Bayesian validation model was fit using 13,109 observations at the 19 beaches on 430 days between 2015 and 2019. The posterior distribution of measurement error variance τ^2 had median 0.77 (95% CI, 0.74 to 0.8). This was 30% of the variance of daily means \bar{Y}_{jt} of 2.5. Complete results of the fit are included in the supplementary material.

³³¹ During the 2019 season 3,780 qPCR measurements were made over 102 days. ³³² The Bayesian posterior FIB level θ is displayed in figure 1. We restricted the test period to those days with two samples at each of the 19 beaches. There were 67 such
 days.

Using the geometric mean FIB level on each beach-day, the median FIB level was 92 CE/mL and 4.9% of these beach-days were in exceedance of the 1000 CE threshold. The Bayesian estimate of the median level was 93 CE (95% CI, 88 to 99 CE) with 3.9% (95% CI, 3.1% to 4.7%) of beach days exceeded the threshold.

We first compare all three validation methods' estimates of MSE since this is the only metric where the non-parametric method is applicable. Then we compare Bayesian and naive estimates of all prediction performance metrics.

342

3.1 Mean squared error under all validation methods

We start by examining the three validation methods on the metric where they can all be compared, namely MSE. Figure 3(A) presents these estimates. While naive validation gives point estimates, non-parametric and Bayesian validation give distributions. Moreover, the latter give joint distributions of MSE for the two prediction models and so yield distributions for the difference in MSE between the two prediction models.

There are four findings here. First, we anticipated that naive validation would give a positively biased estimate of mean-squared error (4) and we see that it does give larger estimates than both non-parametric and Bayesian validation. For both RF and NN prediction models, the naive estimates of MSE lie above the 95% intervals estimated by non-parametric validation. Because non-parametric validation accounts for measurement error, we are inclined to trust its results and dismiss naive validation which is a priori flawed.

Second, we find as expected (equation 7) that while naive validation overstates the MSE of both prediction models, the estimated *difference* between the prediction models agrees with the difference given by non-parametric validation.

Third, we find remarkable agreement between non-parametric and Bayesian MSE estimates. Because non-parametric validation makes few assumptions, this agreement provides evidence to support our use of the Bayesian validation method to further explore the performance of prediction models and metrics for which we do not have a non-parametric method (discussed next).

Fourth, the Bayesian method provides narrower uncertainty around its estimates than the non-parametric method. This may be explained by the fact that when estimating the squared error of a given prediction $\hat{\theta}_{jt}$, the non-parametric method only uses the measurements Y_{ijt} at the site while the Bayesian method uses the additional information of covariates and measurements at other sites.

369

3.2 All performance measures under naive and Bayesian validation

We proceed to evaluate the full set of performance metrics using Bayesian and naive validation methods. We started by using Bayesian validation to estimate the expected sensitivity of the NN prediction model with a binary classification threshold of 1000 CE. The estimate was 95.6%, and to match this (section 2.2.3), a threshold of 440 for the RF was calibrated. Estimates for all prediction performance metrics are shown in figure 3(B).

According to both naive and Bayesian validation, RF outperforms NN in all metrics. However, the discrepancy between Bayesian and naive validation, first documented for MSE in section 3.1 above, continues here across more metrics. Unlike MSE which was systematically overestimated (i.e. pessimistic) using naive validation,

(B) All performance metrics in naive and Bayesian validation

Figure 3: (A) Mean squared error of nearest neighbor and random forest predictions and their difference estimated using naive, non-parametric, and Bayesian validation methods. (B) Prediction performance estimates using naive and Bayesian validation. Solid dots and intervals show median and 50% and 95% credible intervals, respectively, using simulation to account for measurement error. Open squares show naive estimates without accounting for measurement error. Abbreviations: mean squared error (MSE), mean absolute error (MAE), area under receiver operating characteristic curve (AUC).

other measures are variously pessimistic and optimistic, such as when naive validation estimates the precision of the RF to be 0.45 while the Bayesian point estimate is 0.36.

However, as for MSE above, for each metric the bias of naive validation (relative to Bayesian validation) is the same for both RF and NN. Naive estimates of the *difference* in prediction performance benefit from this consistency in that the biases of the difference estimates are not larger than those of the absolute estimates. However, the discrepancy between naive and Bayesian validation of these estimated differences can still be quite large, as for example sensitivity where naive validation estimates RF to be an improvement of 0.27 while the Bayesian estimate is 0.37.

The discrepancy between naive and Bayesian validation turns out to be greatest for MSE and MAE which measure performance of continuous FIB level predictions, and less for the others which measure binary prediction performance.

While the Bayesian estimates of MSE and MAE are relatively precise, the estimates of precision and sensitivity are very uncertain. This is explained by the fact that exceedances (positive events) form the denominator in the sensitivity metric and contribute to the numerator in precision. As a tail event defined by a sharp threshold, exceedance is difficult to measure and model precisely.

These metrics as well as their uncertainty capture the efficacy of the predictions for binary management decision making such as issuing a swim advisory or closing a site. Sensitivity for example is the proportion of elevated FIB events that are correctly predicted (and hence acted on), which for the RF is 0.50 (95% CI, 0.33 to 0.69). Precision on the other hand is the proportion of predicted elevated FIB events (hence actions taken) that are correct, which for the RF is 0.36 (95% CI, 0.23 to 0.50).

403 4 Conclusion

The omission of measurement error, specifically in validation, is ubiquitous in the water resources literature (e.g. Dawson and Wilby (2001); Berenguer et al. (2005); Biondi et al. (2012); Lohani et al. (2012); Shortridge et al. (2016)), including prediction models for recreational water quality (e.g. Nevers and Whitman (2011); Francy (2013); Shively et al. (2016); Lucius et al. (2019)). In this technical note we examined the effect of this omission.

For the specific prediction performance metric of MSE we showed that ignoring 410 measurement error biases validation results (equation 4). The size of the bias depends 411 on the size of the measurement error, which is very large in our context of recre-412 ational water quality. Next we contributed two new methods for model validation and 413 inter-comparison that account for measurement error. The first was a non-parametric 414 method making few assumptions but limited to the metric of MSE. The second was a 415 Bayesian method that uses simulations from a parametric model to estimate any per-416 formance metric. We applied these methods to the evaluation of prediction models of 417 FIB levels at beaches in Chicago and found that not accounting for measurement error 418 significantly mis-estimated model performance across a range of metrics. Moreover it 419 failed to quantify the uncertainty of prediction performance. Our non-parametric and 420 Bayesian approaches overcame these issues. 421

Accurate model skill assessments are important. These estimates are required by water quality managers to understand the utility of model predictions for decisionmaking. Bias in estimated performance metrics could skew how decision-makers interpret model predictions or select among competing models, as could the presentation (or lack thereof) of performance uncertainty. More generally, performance estimates and their uncertainty are essential to understanding the public health consequences of management decisions made on the basis of these models. Measures of model performance are also used to inform decisions about additional sampling (if deemed necessary
to improve performance), which could be costly. For example, if the city of Chicago
were to conclude based on an assessment of model performance that they needed two
samples per beach-day at the 19 beaches, rather than the current proposal which includes roughly half the number of samples, the additional sampling cost would total
about \$57,000 per season assuming an estimated qPCR analysis cost of \$30 per sample
(Griffith & Weisberg, 2011).

Both the non-parametric and Bayesian approaches to validation proposed in this study help overcome limitations of a naive approach. However, the Bayesian approach to validation is more flexible in its ability to compare models across a variety of metrics, some of which might be particularly relevant to decision-making (e.g., predictions of exceedances over a water quality threshold).

Additional developments could improve the Bayesian model. Temporal auto-441 correlation was considered but initial testing (not shown) confirmed previous findings 442 that system dynamics are too fast (Dorevitch et al., 2017). The regression coefficients 443 β_{ik} could be modeled as correlated using a multivariate normal distribution. A more 444 sophisticated approach to spatial correlation is also possible, e.g. using an adjacency 445 matrix within a conditional autoregressive model (Gelfand et al., 2010). There is 446 some evidence suggesting that measurement error may vary with the bacteria level 447 (Whitman et al., 2010), which could be modeled using a heteroskedastistic measure-448 ment error. While the measurements in our dataset are only at a single location and 449 time for each beach and date, it has been shown that there is substantial variation 450 spatially within each beach and temporally within each day (Whitman & Nevers, 2004; 451 Boehm, 2007). With the relevant data, our model could be extended to these finer 452 scales. In applications where predictions models produce probabilistic forecasts, the 453 Bayesian validation method could be further developed with performance measures 454 that compare the forecast distribution with the Bayesian posterior. These efforts are 455 left for future work. Importantly though, even if the Bayesian model is not the best 456 prediction model of FIB levels (as compared to, say, a machine learning model), it 457 enables us to incorporate all available information into simulations of uncertain bac-458 teria concentrations. This study shows how those simulations can be used to validate 459 prediction models for more realistic assessments of skill compared to a naive approach. 460

461 Acknowledgments

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors. Thanks to Dan Black, Steven Durlauf, Jeff Johnston, Andrew Gelman, Jim Savage, Jackie Shadlen, and Rob Trangucci for useful conversations. Thanks also to Lucius et al. for transparency about their model and data and assistance in replicating their results. And thanks to the associate editor and reviewers for helpful feedback.

⁴⁶⁸ Datasets used in this research are available from the following websites: bacteria ⁴⁶⁹ test results (https://data.cityofchicago.org/); site-specific rainfall, cloud cover, ⁴⁷⁰ and wind speed data (https://darksky.net); and Lake Michigan water levels at ⁴⁷¹ Calumet Harbor (https://tidesandcurrents.noaa.gov/).
